9 — Abstract -

We study the problem of testing whether a function $f : \mathbb{R}^n \to \mathbb{R}$ is linear (i.e., both additive and homogeneous) 10 in the distribution-free property testing model, where the distance between functions is measured with respect to 11 an unknown probability distribution over \mathbb{R}^n . We show that, given query access to f, sampling access to the 12 unknown distribution as well as the standard Gaussian, and $\varepsilon > 0$, we can distinguish additive functions from 13 functions that are ε -far from additive functions with $O\left(\frac{1}{\varepsilon}\log\frac{1}{\varepsilon}\right)$ queries, independent of n. Furthermore, under 14 the assumption that f is a continuous function, the additivity tester can be extended to a distribution-free tester 15 for linearity using the same number of queries. On the other hand, we show that if we are only allowed to get 16 values of f on sampled points, then any distribution-free tester requires $\Omega(n)$ samples, even if the underlying 17 distribution is the standard Gaussian. 18

²⁵ 1 Introduction

Property testing of Boolean functions studies the problem where, given query access to a function 26 $f: \{0,1\}^n \to \{0,1\}$ and a parameter $\varepsilon > 0$, the goal is to distinguish with high probability the case 27 that f satisfies some predetermined property P from the case that f is ε -far from satisfying P. That 28 is, whether we need to change the values of f(x) for at least an ε -fraction of $x \in \{0,1\}^n$ before f 29 satisfies P. Since the seminal work by Blum, Luby and Rubinfeld [11], property testing has become 30 a thriving field, and many properties of Boolean functions have been shown to be testable with a 31 number of queries independent of n, including linear functions [11], low-degree polynomials [8,26] 32 and k-juntas [9, 10, 18]. For an introductory survey, we recommend [21]. 33

In contrast to Boolean functions, only a few properties of functions on a Euclidean space, that is, \mathbb{R}^n , have been studied. For a measurable function $f: \mathbb{R}^n \to \mathbb{R}, \varepsilon > 0$, and a property P, we say that f is ε -far from P if

Pr
$$_{x \sim \mathcal{N}(0,I)}[f(x) \neq g(x)] > \varepsilon,$$

for any measurable function $g: \mathbb{R}^n \to \mathbb{R}$ satisfying P, where $\mathcal{N}(0, I)$ is the standard Gaussian. We say that an algorithm is a *tester* for a property P if, given query access to a measurable function

22:2 Distribution-Free Testing of Linear Functions on \mathbb{R}^n

⁴⁰ $f: \mathbb{R}^n \to \mathbb{R}$, sampling access to the standard Gaussian, and $\varepsilon > 0$, it accepts with probability ⁴¹ at least 2/3 when f satisfies P, and rejects with probability at least 2/3 when f is ε -far from P. ⁴² Testability of a variety of properties has been considered, including surface area of a set [29, 34], half ⁴³ spaces [31–33], linear separators [3], high-dimensional convexity [13], and linear k-junta [15].

Although the standard Gaussian is natural, it rarely appears in practice. In fact, we typically have little, if any, information about the underlying distribution. This raises the question of whether we can test when the underlying distribution of the data is unknown. For a measurable function $f : \mathbb{R}^n \to \mathbb{R}$, $\varepsilon > 0$, a distribution \mathcal{D} over \mathbb{R}^n , and a property P, we say that f is ε -far from P with respect to \mathcal{D} if

48
$$\Pr_{x \sim \mathcal{D}}[f(x) \neq g(x)] > \varepsilon,$$

for any measurable function $g: \mathbb{R}^n \to \mathbb{R}$ satisfying P. We say that an algorithm is a *distribution-free tester* for a property P if, given query access to a measurable function $f: \mathbb{R}^n \to \mathbb{R}$, sampling access to an *unknown* distribution \mathcal{D} over \mathbb{R}^n as well as the standard Gaussian, and $\varepsilon > 0$, it accepts with probability at least 2/3 when f satisfies P, and rejects with probability at least 2/3 when f is ε -far from P with respect to \mathcal{D} . Distribution-free property testing is an attractive model because it makes minimal assumptions on the environment, and models the scenario most often occurring in practice. We say that a function $f: \mathbb{R}^n \to \mathbb{R}$ is *additive* if f(x) + f(y) = f(x+y) for any $x, y \in \mathbb{R}^n$. In

this work, we consider distribution-free testing of additivity of functions $f : \mathbb{R}^n \to \mathbb{R}$ and show the following.

Theorem 1. There exists a one-sided error distribution-free tester for additivity of $f : \mathbb{R}^n \to \mathbb{R}$ with $O\left(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$ queries.

Previously no algorithm was known even when the underlying distribution \mathcal{D} is the standard Gaussian. As there is a trivial lower bound of $\Omega\left(\frac{1}{\varepsilon}\right)$, the query complexity of our tester is almost tight.

We say that a function $f: \mathbb{R}^n \to \mathbb{R}$ is *homogeneous* if cf(x) = f(cx) for any $x \in \mathbb{R}^n$ and $c \in \mathbb{R}$. A function that is both additive and homogeneous is said to be *linear*. Although additivity and linearity are equivalent for functions over finite groups, there are (pathological) functions $f: \mathbb{R}^n \to \mathbb{R}$ that are additive but not homogeneous. Hence, the testability of additivity does not immediately imply the testability of linearity. However, when the input function is guaranteed to be continuous, we can also test linearity.

Theorem 2. Suppose that the input function is guaranteed to be continuous. Then, there exists a one-sided error distribution-free tester for linearity with $O\left(\frac{1}{\varepsilon}\log\frac{1}{\varepsilon}\right)$ queries.

It is also natural to assume that we can get values of the input function only on sampled points. Specifically, we say that a (distribution-free) tester is *sample-based* if it accesses the input function $f: \mathbb{R}^n \to \mathbb{R}$ through points sampled from the distributions \mathcal{D} and $\mathcal{N}(0, I)$. We show a strong lower bound for sample-based testers.

Theorem 3. Any sample-based tester for the linearity of functions $f : \mathbb{R}^n \to \mathbb{R}$ requires $\Omega(n)$ samples, even when $\mathcal{D} = \mathcal{N}(0, I)$.

This lower bound is tight; it is not difficult to see that O(n) samples suffices to test linearity. Indeed O(n) samples will, with high probability, contain n linearly independent vectors. The evaluations of f on these vectors uniquely determines the linear function. This theorem shows a sharp contrast between query-based and sample-based testers for properties of functions on a Euclidean space. We note that we can show the same lower bound for testing additivity with an almost identical proof.

81 1.1 Related Work

The question of property testing first appeared (implicitly) in the work of Blum, Luby and Ru-82 binfeld [11]. Among the problems that they studied was linearity testing. Their algorithm, now 83 famously known as the BLR test, has played a key role in the design of probabilistically checkable 84 proofs [2, 5, 25] and this connection was some of the early motivation for the field of property testing. 85 86 Since the original paper, the parameters of the BLR test have been extensively refined. Much of this work focused on reducing the amount of randomness, due to this being a key parameter in probabilist-87 ically checkable proofs, as well as analyzing the rejection probability (see [36] for a survey). Another 88 line of works considered the testing linearity over more general domains. The works of [7, 11, 35] 89 showed that the BLR test can be used to test the linearity of any function with $f: G \to H$ for finite 90 groups G and H with $O(1/\varepsilon)$ queries. Following this, a body of work [1, 17, 19, 27] constructed 91 testers for linearity of functions $f: S \to \mathbb{R}$, where S is a finite subset of rational numbers, and the 92 distance is measured with respect to the uniform distribution over S. See [28] for a survey. These 93 results were phrased in terms of approximate self-testing and correcting programs. In this setting 94 the queries to f return a finite approximation of f(x). Although these results are arguably the most 95 related to our work, our proof differs significantly from theirs and instead takes inspiration from the 96 original BLR test. 97 Distribution-free testing (for graph properties) was first defined by Goldreich et al. [22], though 98

the first distribution-free testers for non-trivial properties appeared much later in the work of Halevy 99 and Kushilevitz [23]. Subsequently, distribution-free testers have been considered for a variety 100 of Boolean functions including low-degree polynomials, dictators, and monotone functions [23], 101 k-juntas [6, 12, 23, 30], conjunctions, decision lists, and linear threshold functions [20], monotone and 102 non-monotone monomials [16], and monotone conjunctions [14, 20]. However, to our knowledge 103 the only (partial) distribution-free tester for a class of functions on the Euclidean space is due to 104 Harms [24] who gave an efficient tester for half spaces, that is, functions $f : \mathbb{R}^n \to \{0, 1\}$ of the form 105 $f(x) = \operatorname{sgn}(w^{\top}x - \theta)$ for some $w \in \mathbb{R}^n$ and $\theta \in \mathbb{R}$, over any rotationally invariant distribution. 106

107 1.2 Proof Technique

The construction of our tester for additivity will be done in two steps. First, we construct a constant-108 query tester for additivity over the standard Gaussian distribution $\mathcal{N}(0, I)$. Our tester will accept 109 linear functions with probability 1, and so the majority of the work is in showing that if the test 110 accepts the given function $f : \mathbb{R}^n \to \mathbb{R}$ with high probability, then f is close to an additive function. 111 To do so, we show that if f passes a series of tests then there exists a related function $q \colon \mathbb{R}^n \to \mathbb{R}$, 112 defined from f, which is additive. Furthermore, if f is linear then f = q. The definition of q will 113 allow us to obtain query access to it with high probability, and so we can simply estimate the distance 114 between f and g. At a high-level, this is somewhat similar to the BLR test, however operating over 115 $\mathcal{N}(0, I)$ rather than the uniform distribution presents its own set of non-trivial challenges. We discuss 116 these, as well as the definition of g at the start of Section 3.1. 117

It is fairly straightforward to generalize this tester for additivity to a distribution-free tester. To do so, we run the additivity tester for the standard Gaussian, except that testing the distance between fand g will now be done using samples from the unknown \mathcal{D} . This crucially relies on our ability to draw samples from the standard Gaussian.

Any additive function $f: \mathbb{R}^n \to \mathbb{R}$ is linear over the rationals, meaning that f(qx) = qf(x)for every $q \in \mathbb{Q}$. Therefore, in order to test linearity it remains to test whether this holds also for irrationals. Assuming that f is continuous we are able to modify our tester to show that this implies that the additive function g is continuous as well. We then leverage the fact that any continuous additive function is linear in order to obtain our linearity tester.

22:4 Distribution-Free Testing of Linear Functions on \mathbb{R}^n

To prove Theorem 3, the lower bound on sample-based testers for linearity, we construct two 127 distributions, one supported on linear functions, and the other supported on functions which are 128 far from linear. Consider drawing a function f from one of these two distributions with equal 129 probability. By Yao's minimax principle it suffices to show that any deterministic algorithm which 130 receives n samples from $\mathcal{N}(0, I)$, together with their evaluations on f, is unable to distinguish, with 131 high probability, which of the two distribution f came from. To construct the distribution on linear 132 functions, we sample $w \sim \mathcal{N}(0, I)$ and return $f(x) := w^{\top} x$. Our distribution on functions which are 133 far from linear is designed so that any function f from this distribution satisfies $f(x+y) \neq f(x) + f(y)$ 134 with probability 1 over $x, y \sim \mathcal{N}(0, I)$. To do so, for every $x \in \mathbb{R}^n$ we sample ε_x from a one-135 dimensional Gaussian and return $f(x) := w^{\top} x + \varepsilon_x$. It is not difficult to show that such functions 136 are far from linear. 137

138 1.3 Organization

The remainder of the paper is organized as follows. In Section 2 we review several useful facts about probability distributions. In Section 3 we develop our distribution-free tester for additivity by first constructing a tester for additivity over the standard Gaussian in Section 3.1. We generalize this tester to the distribution-free setting in Section 3.2 and to a tester for linearity in Section 4. Finally, we end with our lower bound on the sampling model in Section 5.

144 **2** Preliminaries

Let \mathcal{D} and \mathcal{D}' be probability distributions on the same domain Ω . Then, the *total variation distance* between them, denoted by $d_{TV}(\mathcal{D}, \mathcal{D}')$, is defined as

¹⁴⁷
$$d_{\mathrm{TV}}(\mathcal{D}, \mathcal{D}') := \frac{1}{2} \int_{\Omega} |\mathcal{D}(x) - \mathcal{D}'(x)| dx.$$

The *Kullback-Leibler divergence* (or *KL-divergence*) of \mathcal{D}' from \mathcal{D} , denoted $d_{\mathrm{KL}}(\mathcal{D} \| \mathcal{D}')$, is defined as

¹⁵⁰
$$d_{\mathrm{KL}}(\mathcal{D}||\mathcal{D}') = \int_{\Omega} \mathcal{D}(x) \log\left(\frac{\mathcal{D}(x)}{\mathcal{D}'(x)}\right) dx.$$

¹⁵¹ We will use the KL-divergence to upper bound the total variation distance, using the following ¹⁵² inequality.

Theorem 4 (Pinsker's Inequality). Let \mathcal{D} and \mathcal{D}' be probability distributions on the same domain Ω . Then,

155
$$d_{\mathrm{TV}}(\mathcal{D}, \mathcal{D}') \leq \sqrt{\frac{1}{2} d_{\mathrm{KL}}(\mathcal{D} \| \mathcal{D}')}.$$

¹⁵⁶ The following allows us to bound the KL-divergence between two Gaussian distributions.

▶ **Lemma 5.** Let $\mathcal{D} = \mathcal{N}(\mu_1, \Sigma_1)$ and $\mathcal{D}' = \mathcal{N}(\mu_2, \Sigma_2)$ be multivariate Gaussian distributions with $\mu_1, \mu_2 \in \mathbb{R}^n$ and invertible $\Sigma_1, \Sigma_2 \in \mathbb{R}^{n \times n}$. Then,

¹⁵⁹
$$d_{\mathrm{KL}}(\mathcal{D}\|\mathcal{D}') = \frac{1}{2} \left(\log \left(\frac{\det \Sigma_2}{\det \Sigma_1} \right) + \operatorname{tr} \left((\Sigma_2)^{-1} \Sigma_1 \right) - n + (\mu_2 - \mu_1)^\top \Sigma_2^{-1} (\mu_2 - \mu_1) \right).$$

We record a useful lemma about total variation distance of Gaussians with shared covariance matrices.

162 **Lemma 6.** Consider two Gaussian distributions $\mathcal{N}(\mu_1, \Sigma), \mathcal{N}(\mu_2, \Sigma)$ with shared invertible 163 covariance matrices $\Sigma \in \mathbb{R}^{n \times n}$. Then $d_{\text{TV}}(\mathcal{N}(\mu_1, \Sigma), \mathcal{N}(\mu_2, \Sigma)) \leq \phi$ holds if $\|\mu_1 - \mu_2\|_2 \leq$ 164 $2\phi/\sqrt{\|\Sigma^{-1}\|_2}$.

Proof. Denote $\mu := \mu_1 - \mu_2$. By Lemma 5, $d_{\mathrm{TV}}(\mathcal{N}(\mu_1, \Sigma), \mathcal{N}(\mu_2, \Sigma)) = \sqrt{\frac{1}{4}\mu^\top \Sigma^{-1}\mu}$. Now, because Σ is PSD, $\mu^\top \Sigma^{-1}\mu \leq \|\mu\|_2^2 \|\Sigma^{-1}\|_2$, where $\|\cdot\|_2$ is the spectral matrix norm. Therefore, we have $d_{\mathrm{TV}}(\mathcal{N}(\mu_1, \Sigma), \mathcal{N}(\mu_2, \Sigma)) \leq \frac{1}{2} \|\mu\|_2 \sqrt{\|\Sigma^{-1}\|_2} \leq \phi$.

3 Testing Additivity

In this section, we develop our distribution-free tester for additivity. For convenience, we first describe a simpler tester for additivity over the standard Gaussian distribution $\mathcal{N}(0, I)$ in Section 3.1. Then, in Section 3.2, we describe how to generalize this algorithm to test additivity over an unknown distribution.

3.1 Tester for the Standard Gaussian

Our goal in this section is to design a constant-query tester for the additivity of a measurable function $f: \mathbb{R}^n \to \mathbb{R}$ over the standard Gaussian.

Theorem 7. There exists a one-sided error $O\left(\frac{1}{\varepsilon}\log\frac{1}{\varepsilon}\right)$ -query tester for additivity over the standard Gaussian.

At a high-level, our tester consists of two steps. First, we test whether f satisfies additivity over a set of samples drawn from the distribution. If f passes this test, then we conclude that there must be an additive function $g: \mathbb{R}^n \to \mathbb{R}$, which is a self-corrected version of f. Second, by testing the value of f on a correlated set of points, we are able to get query access to g with high probability, and therefore we can simply estimate the distance between f and g. Our tester relies on the fact that it has one-sided error: if f is additive then our test passes with probability 1. Otherwise, if f is non-additive and the second step passes with high probability, then f and g must be close.

The first step is inspired by the BLR test. Indeed, the evaluation of the function g at a point 186 p is defined as the (weighted) majority value of f(p-x) + f(x) over all $x \sim \mathcal{N}(0, I)$ (where, 187 f(p-x) + f(x) is weighted according to the probability of drawing $x \sim \mathcal{N}(0, I)$). However, there 188 are some significant challenges in generalizing the BLR test to the standard Gaussian, the most 189 obvious of which is that unlike the uniform distribution, every point in the support of the distribution 190 does not have equal probability. In particular, p - x is not distributed as $x \sim \mathcal{N}(0, I)$ for fixed $p \neq 0$. 191 In order to overcome this, we exploit the fact that for additive functions f, we have f(x) = qf(x/q)192 for every rational q. This allows us to restrict attention to a small ball B(0, 1/r) of radius 1/r centered 193 at the origin. Then, for $p \in B(0, 1/r)$, p - x is approximately distributed as x for small enough 1/r. 194 Thus, we get around the issue of unevenly weighted points by defining g within B(0, 1/r), and then 195 extrapolating to define g over \mathbb{R}^n . 196

¹⁹⁷ Concretely, we will define g as follows. First, let r be a sufficiently large integer (r = 50 suffices). ¹⁹⁸ For each point $p \in \mathbb{R}^n$ define

199
$$k_p := \begin{cases} 1 & \text{if } \|p\|_2 \le 1/r, \\ \lceil r \cdot \|p\|_2 \rceil & \text{if } \|p\|_2 > 1/r. \end{cases}$$

Now, define $g \colon \mathbb{R}^n \to \mathbb{R}$ as

$$g(p) := k_p \cdot \min_{\mathcal{N}(0,I)} \left[f\left(\frac{p}{k_p} - x\right) + f(x) \right],$$

Algorithm 1: Standard Gaussian Additivity Tester

Given :Query access to $f : \mathbb{R}^n \to \mathbb{R}$, sampling access to the distribution $\mathcal{N}(0, I)$;

1 **Reject** if TESTADDITIVITY(f) returns **Reject**;

- 2 for $N_1 := O(1/\varepsilon)$ times do
- 3 | Sample $p \sim \mathcal{N}(0, I)$;
- 4 **Reject** if $f(p) \neq QUERY-g(p, f)$ or if QUERY-g(p, f) returns **Reject**.
- 5 Accept.

Algorithm 2: Subroutines

```
1 Procedure TESTADDITIVITY(f)
        Given :Query access to f : \mathbb{R}^n \to \mathbb{R}, sampling access to the distribution \mathcal{N}(0, I);
2
        for N_2 := O(1) times do
             Sample x, y, z \sim \mathcal{N}(0, I);
 3
             Reject if f(-x) \neq -f(x);
 4
             Reject if f(x - y) \neq f(x) - f(y);
 5
             Reject if f\left(\frac{x-y}{2}\right) \neq f\left(\frac{x-z}{2}\right) + f\left(\frac{z-y}{2}\right);
 6
        Accept.
 7
8 Procedure QUERY-g(p, f)
        Given : p \in \mathbb{R}^n, query access to f : \mathbb{R}^n \to \mathbb{R}, sampling access to \mathcal{N}(0, I);
        N_2' := O(\log \frac{1}{\varepsilon});
9
        Sample x_1, \ldots, x_{N'_2} \sim \mathcal{N}(0, I);
10
        Reject if there exists i, j \in [N'_2] such that
11
          f(p/k_p - x_i) + f(x_i) \neq f(p/k_p - x_j) + f(x_j);
        return k_p (f(p/k_p - x_1) + f(x_1)).
12
```

where maj_{$\mathcal{N}(0,I)$} is the *weighted majority function* where a value $f(p/k_p - x) + f(x)$ is weighted according to its probability mass under $x \sim \mathcal{N}(0, I)$. Observe that either $p \in B(0, 1/r)$, or g(p) first maps p to a point p/k_p in B(0, 1/r). The value of g is the most likely value (according to $\mathcal{N}(0, I)$) of $f(p/k_p - x) + f(x)$. If f is close to additive, then taking this majority should allow us to correct for the errors in f.

An equivalent definition of g which will be useful is the following. For $p \in \mathbb{R}^n$ let P_p be the Lebesgue measurable function such that $\int_A P_p(x) dx$ gives the probability (over $\mathcal{N}(0, I)$) that $f(p/k_p - x) + f(x)$ takes value in A. Then g is defined as $g(p) := \operatorname{argmax}_x P_p(x)$ if $P_p(x) \ge 1/2$.

Our algorithm is given in Algorithm 1, which uses subroutines given in Algorithm 2. The QUERYg subroutine allows us to obtain query access to g with high probability, while the TESTADDITIVITY subroutine tests the conditions that we require in order to prove that g is additive.

▶ Lemma 8. If TESTADDITIVITY(f) accepts with probability at least 1/10, then g is a well-defined, additive function, and furthermore, $\Pr_{x \sim \mathcal{N}(0,I)}[g(p) \neq k_p(f(p/k_p - x) + f(x))] < 1/2$.

²¹⁵ We first prove Theorem 7 assuming that Lemma 8 holds.

Proof of Theorem 7. First, observe that if f is an additive function then Algorithm 1 always accepts. Indeed, it is immediate that TESTADDITIVITY(f) always accepts. To see that f also passes the remaining tests, observe that by additivity, $k_p (f(p/k_p - x) + f(x)) = k_p f(p/k_p) = f(p)$,

where the final inequality holds because $k_p \in \mathbb{Z}$ and by homogeneity over the rationals f(qx) = qf(x)219 for every $q \in \mathbb{Q}$. 220

We now show that if f is ε -far from all additive functions then Algorithm 1 rejects with probability 221 at least 2/3. If TESTADDITIVITY(f) accepts with probability at most 1/10, we can reject f with 222 probability at least 1 - 1/10 > 2/3. Hence, we assume that TESTADDITIVITY(f) accepts with 223 probability at least 1/10. Then by Lemma 8, the function g is additive and hence f is ε -far from g. 224 Now, we want to bound the probability that Step 2 of Algorithm 1 passes. 225

First, we bound the probability that QUERY-g(p, f) fails to recover the value of g(p). That is, 226 we bound the probability that $f(p/k_p - x_i) + f(x_i) = f(p/k_p - x_j) + f(x_j)$ for all $i, j \in [N'_2]$, 227 but $g(p) \neq k_p (f(p/k_p - x_i) + f(x_i))$. By Lemma 8, the probability that we draw N'_2 points which 228 satisfy this is at most $2^{-N'_2} \leq \varepsilon/2$ by choosing the hidden constant in N'_2 to be large enough. 229 Therefore, the probability that we correctly recover g(p) is at least $1 - \varepsilon/2$. 230

Now that we have established that we can obtain query access to q with high probability, it 231 remains to show that we can test whether f and q are close. Indeed, the probability that Step 2 of 232 Algorithm 1 fails to reject is at most 233

$$\begin{cases} \Pr_{p \sim \mathcal{N}(0,I)} \left[f(p) = g(p) \lor \text{QUERY-} g(p,f) \text{ fails to correctly recover } g(p) \right] \end{pmatrix}^{N_1} \\ \leq \left(1 - \Pr_{p \sim \mathcal{N}(0,I)} \left[f(p) \neq g(p) \right] + \Pr_{p \sim \mathcal{N}(0,I)} \left[\text{QUERY-} g(p,f) \text{ fails to correctly recover } g(p) \right] \right)^{N_1} \\ < \left(1 - \frac{\Gamma}{2} \right)^{N_1} < \frac{1}{10}, \end{cases}$$

237

by choosing the hidden constant in N_1 to be large enough. Therefore, Algorithm 1 rejects with 238 probability at least 1 - 1/10 > 2/3. 239

It remains to prove Lemma 8 showing that if Algorithm 1 succeeds, then g is an additive function 240 with high probability. 241

Additivity of the Function q 3.1.1 242

First, we record the basic, but useful observation that if the TESTADDITIVITY subroutine passes then 243 each of its tests hold with high probability over $\mathcal{N}(0, I)$. 244

Lemma 9. If TESTADDITIVITY(f) accepts with probability at least 1/10, then 245

$$\Pr_{x,y\sim\mathcal{N}(0,I)} \left[f(x-y) = f(x) - f(y) \right] \ge \frac{99}{100},\tag{1}$$

247

248 249

246

$$\Pr_{x,y,z\sim\mathcal{N}(0,I)}\left[f\left(\frac{x-y}{2}\right) = f\left(\frac{x-z}{2}\right) + f\left(\frac{z-y}{2}\right)\right] \ge \frac{99}{100}.$$
(3)

 $\Pr_{x \sim \mathcal{N}(0,I)} [f(-x) = -f(x)] \ge \frac{99}{100},$

Proof. Suppose for contradiction that at least one of (1), (2), and (3) does not hold. We here assume 250 that (1) does not hold as other cases are similar. 251

We accept only when all the sampled pairs (x, y) satisfy f(x + y) = f(x) + f(y). By setting the 252 hidden constant in N_2 to be large enough, this happens with probability at most 253

254
$$\left(1 - \Pr_{x, y \sim \mathcal{N}(0, I)}[f(x+y) \neq f(x) + f(y)]\right)^{N_2} < \left(\frac{99}{100}\right)^{N_2} < \frac{1}{10},$$

which is a contradiction. 255

(2)

22:8 Distribution-Free Testing of Linear Functions on \mathbb{R}^n

In order to argue that g is additive, we will first argue that g is additive on points within the tiny ball B(0, 1/r). To do so, we will crucially use the fact that p - x is distributed approximately as $x \sim \mathcal{N}(0, I)$ if $||p||_2$ is small. By Lemma 6 we have a bound on the total variation distance between x and x + p.

²⁶⁰ \triangleright Claim 10. Let $p \in \mathbb{R}^n$ satisfying $||p||_2 \leq k/r$ for some $k \in \mathbb{Z}^{>0}$. Then $d_{TV}(\mathcal{N}(0, I), \mathcal{N}(p, I)) \leq k/100$.

Proof. By Lemma 6, for $d_{TV}(\mathcal{N}(0,I),\mathcal{N}(p,I)) \leq k/100$ it is enough to show that p satisfies $\|0-p\|_2 \leq 2k/(100\sqrt{\|I\|_2})$. Because $\|p\|_2 \leq k/r \leq 2k/100 = 2k/(100\sqrt{\|I\|_2})$.

After arguing that g is additive in B(0, 1/r), it will follow that g is additive elsewhere because gis defined by extrapolating the value of g within this ball. Therefore, we will focus on proving the additivity of g within B(0, 1/r).

▶ **Lemma 11.** Suppose that (1) – (3) of Lemma 9 hold. For every $p, q \in \mathbb{R}^n$ with $||p||_2, ||q||_2, ||p + q||_2 \le 1/r$ it holds that g(p+q) = g(p) + g(q).

The proof of this lemma will crucially rely on the following two lemmas, which say that the conclusions of Lemma 9 hold with high probability even when one of the points are fixed to a point B(0, 1/r). A consequence of this is that g is well-defined.

▶ Lemma 12. Suppose that (1) – (3) of Lemma 9 hold, then g is well-defined, and for every $p \in \mathbb{R}^n$ with $||p||_2 \leq 1/r$,

274
$$\Pr_{x \sim \mathcal{N}(0,I)}[g(p) = f(p-x) + f(x)] \ge \frac{9}{10}.$$

Proof. Fix a point $p \in \mathbb{R}^n$ with $||p||_2 \le 1/r$. We will bound the following probability.

276
$$A := \Pr_{x, y \sim \mathcal{N}(0, I)} [f(p - x) + f(x) = f(p - y) + f(y)]$$

277 Observe that

278
$$A = \Pr_{x, y \sim \mathcal{N}(0, I)} [f(x) - f(y) \neq f(p - y) - f(p - x)]$$

$$\leq \Pr_{x,y \sim \mathcal{N}(0,I)} [f(x) - f(y) \neq f(x-y)] + \Pr_{x,y \sim \mathcal{N}(0,I)} [f(x-y) \neq f(p)]$$

$$< \frac{1}{100} + \Pr_{x,y \sim \mathcal{N}(0,I)} [f(x-y) \neq f(p-y) - f(p-x)]$$

280 281

It remains to bound the second term. Intuitively, because $x - p, y - p \sim \mathcal{N}(-p, I)$ and $p \approx 0$, the random variables p - x and p - y should be distributed similarly to x and y. Indeed,

(-y) - f(p-x)]

(By Lemma 9)

284
$$\Pr_{x,y \sim \mathcal{N}(0,I)}[f(x-y) \neq f(p-y) - f(p-x)]$$

285
$$= \Pr_{x,y \sim \mathcal{N}(0,I)} [f(x-p+p-y) \neq f(p-y) - f(p-x)]$$

286
$$= \Pr_{x, y \sim \mathcal{N}(-p, I)} [f(x - y) \neq f(-y) - f(-x)]$$

$$\sum_{x,y \sim \mathcal{N}(0,I)} \Pr[f(x-y) \neq f(-y) - f(-x)] + 2 d_{\mathrm{TV}} \left(\mathcal{N}(0,I), \mathcal{N}(-p,I) \right)$$

$$\leq \Pr_{x,y \sim \mathcal{N}(0,I)} [f(x-y) \neq f(x) - f(y)] + \frac{2}{100} + 2\Pr_{x \sim \mathcal{N}(0,I)} [f(-x) \neq f(x)]$$
 (Claim 10)

$$\leq \frac{1}{100} + \frac{1}{100} = \frac{1}{100}$$
. (By (1) and (2) in Lemma 9)

Plugging this into our previous bound on A, we can conclude that 291

292
$$A \ge 1 - \left(\frac{1}{100} + \frac{5}{100}\right) = 1 - \frac{6}{100} > \frac{9}{10}$$

Next, we bound A above in terms of the probability that $g(p) \neq f(p-x) + f(x)$. Define 293 $P_p \colon \mathbb{R}^n \to \mathbb{R}^+$ to be the bounded Lebesgue-measurable function such that $\int_B P_p(x) dx$ is the 294 probability that f(p-x) + f(x) takes value in the (measurable) set B. By Hölder's inequality with 295 $p = 1, q = \infty$ we have 296

297
$$A = \int_{\mathbb{R}} P_p^2(x) dx \le \|P_p\|_{\infty} \int_{\mathbb{R}} P_p(x) dx = \|P_p\|_{\infty},$$

where the last equality follows because P_p is a density and $\int_{\mathbb{R}} P_p(x) dx = 1$ holds. Therefore, 298

299
$$\frac{9}{10} \le A \le \|P_p\|_{\infty}.$$

Because $\operatorname{argmax}_x P_p(x) \ge 9/10 > 1/2$, we have $g(p) = \operatorname{argmax}_x P_p(x)$ and hence $\operatorname{Pr}_{x \sim \mathcal{N}(0,I)}[g(p) = 0]$ 300 $f(p-x) + f(x) \ge 9/10.$ 301

The following lemma is essentially condition (3) of Lemma 9 with two fixed points. 302

▶ Lemma 13. Suppose that (1)–(3) of Lemma 9 hold then, for every $p, q \in \mathbb{R}^n$ with $||p||_2, ||q||_2, ||p+||_2 = 1$ 303 $q \parallel \leq 1/r$, 304

$$\Pr_{x,y,z\sim\mathcal{N}(0,I)}\left[g(p+q)\neq f\left(p-\frac{x-z}{2}\right)+f\left(q-\frac{z-y}{2}\right)+f\left(\frac{x-y}{2}\right)\right]\leq\frac{2}{10}$$

Proof. Fix a pair of points $p, q \in \mathbb{R}^n$ with $||p||_2, ||q||_2 \leq 1/r$. We can bound the probability 306

$$\sum_{\substack{x,y,z \sim \mathcal{N}(0,I) \\ \text{310}}} \Pr \left[g(p+q) \neq f\left(p+q-\frac{x-y}{2}\right) + f\left(\frac{y}{2}\right) \right]$$

$$+ \Pr_{\substack{x,y,z \sim \mathcal{N}(0,I) \\ \text{310}}} \left[f\left(p+q-\frac{x-y}{2}\right) \neq f\left(p-\frac{x-z}{2}\right) + f\left(q-\frac{z-y}{2}\right) \right]$$

To bound the first term, observe that if $x, y \sim \mathcal{N}(0, I)$, then the random variable (x - y)/2 is also 311 distributed according to $\mathcal{N}(0, I)$. Furthermore, because $\|p + q\|_2 \leq 1/r$, we can apply Lemma 12 312 and conclude that 313

³¹⁴
₃₁₅
$$\Pr_{x,y,z \sim \mathcal{N}(0,I)} \left[g(p+q) \neq f\left(p+q-\frac{x-y}{2}\right) + f\left(\frac{x-y}{2}\right) \right] \leq \frac{1}{10}.$$

x - u

To bound the second term, observe that 316

Г /

$$\Pr_{x,y,z \sim \mathcal{N}(0,I)} \left[f\left(p+q-\frac{x-y}{2}\right) \neq f\left(p-\frac{x-y}{2}\right) + f\left(q-\frac{x-y}{2}\right) \right]$$

$$= \Pr_{x,y,z \sim \mathcal{N}(0,I)} \left[f\left(\frac{(2q+y)-(x-2p)}{2}\right) \neq f\left(\frac{(2q+y)-z}{2}\right) + f\left(\frac{z-(x-2p)}{2}\right) \right]$$

x-z

1

 $z - \eta$

$$= \Pr_{\substack{x \sim \mathcal{N}(-2p,I) \\ y \sim \mathcal{N}(2q,I) \\ z \sim \mathcal{N}(0,1)}} \left[f\left(\frac{y-x}{2}\right) \neq f\left(\frac{y-z}{2}\right) + f\left(\frac{z-x}{2}\right) \right]$$

$$\leq \Pr_{x,y,z \sim \mathcal{N}(0,I)} \left[f\left(\frac{x-y}{2}\right) \neq f\left(\frac{x-z}{2}\right) + f\left(\frac{z-y}{2}\right) \right] + d_{\mathrm{TV}} \left(\mathcal{N}(0,I), \mathcal{N}(-2p,I) \right)$$

$$+ \mathrm{d}_{\mathrm{TV}}\left(\mathcal{N}(0,I),\mathcal{N}(2q,I)\right)$$

$$\leq \frac{1}{100} + \frac{2}{100} + \frac{2}{100} = \frac{5}{100}.$$
 (By Lemma 9 and Claim 10)

ITCS 2020

22:10 Distribution-Free Testing of Linear Functions on \mathbb{R}^n

Combining both of these bounds, we have $\Pr_{x,y,z\sim\mathcal{D}}[g(p+q)\neq f(p-\frac{x-z}{2})+f(q-\frac{z-y}{2})+f$ 324 $f(\frac{x-y}{2}) \le 1/10 + 5/100 \le 2/10.$ 325

The additivity of g within B(0, 1/r) is an immediate consequence of these two lemmas. 326

Proof of Lemma 11. Let $p, q \in \mathbb{R}^n$ be any pair of points satisfying $||p||_2, ||q||_2, ||p+q||_2 \leq 1/r$. 327 Our aim is to show that g(p+q) = g(p) + g(q). By a union bound over Lemmas 12 and 13, the 328 probability that $x, y, z \sim \mathcal{N}(0, I)$ simultaneously satisfy 329

- 1. $g(p+q) = f(p \frac{x-z}{2}) + f(q \frac{z-y}{2}) + f(\frac{x-y}{2}),$ 330
- 2. $g(p) = f(p \frac{x-z}{2}) + f(\frac{x-z}{2}),$ 3. $g(q) = f(q \frac{z-y}{2}) + f(\frac{z-y}{2}),$ 4. $f(\frac{x-y}{2}) = f(\frac{x-z}{2}) f(\frac{z-y}{2})$ 331
- 332
- 333

is at least $1 - (2/10 + 2 \cdot 1/10 + 1/10) > 0$. Here we are using the fact that ((x - y)/2) is distributed 334 as $\mathcal{N}(0, I)$. Fixing such a triple (x, y, z), we conclude that 335

$$g(p+q) = f\left(p - \frac{x-z}{2}\right) + f\left(q - \frac{z-y}{2}\right) + f\left(\frac{x-y}{2}\right)$$

$$g(p+q) = g(p) + g(q) + f\left(\frac{x-y}{2}\right) - f\left(\frac{x-z}{2}\right) - f\left(\frac{z-y}{2}\right)$$

$$g(p) = g(p) + g(q).$$

Therefore q is additive within B(0, 1/r). 340

Finally, we argue that q is additive everywhere. Intuitively this should be true because the values 341 of g on points outside of B(0, 1/r) are defined by extrapolating the values of g on points within 342 B(0, 1/r), where we know g is additive. For the proof, it will be useful to record the following fact. 343

▶ Fact 14. Provided that (1) – (3) of Lemma 9 hold then, for every $p \in \mathbb{R}^n$ with $||p||_2 \le 1/r$ and 344 $c \in \mathbb{Z}^{>0}$, we have g(p) = cg(p/c). 345

Proof. Observe that $g(p) = g((c/c)p) = g(\sum_{i=1}^{c} p/c) = \sum_{i=1}^{c} g(p/c) = c \cdot g(p/c)$, where the 346 third equality follows by Lemma 11, noting that $||kp/c||_2 \leq 1/r$ for every $k \in [c-1]$ 347

Proof of Lemma 8. Fix a pair of points $p, q \in \mathbb{R}^n$, we will argue that g(p+q) = g(p) + g(q). 348 Recall that $g(p) := k_p g(p/k_p), g(q) := k_q g(q/k_q)$, and $g(p+q) := k_{p+q} g((p+q)/k_{p+q})$. Then, 349

$$g(p) + g(q) = k_p \cdot g\left(\frac{p}{k_p}\right) + k_q \cdot g\left(\frac{p}{k_q}\right) = k_p k_q k_{p+q} \cdot g\left(\frac{p}{k_p k_q k_{p+q}}\right) + k_p k_q k_{p+q} \cdot g\left(\frac{p}{k_p k_q k_{p+q}}\right),$$

where the second equality follows by Fact 14, noting that $k_p, k_q, k_{p+q} \in \mathbb{Z}^{>0}$ and so $p/k_p, q/k_q \in$ 351 B(0, 1/r). Furthermore, because $p/(k_p k_q k_{p+q}), q/(k_p k_q k_{p+q}), (p+q)/(k_p k_q k_{p+q}) \in B(0, 1/r),$ 352 we can apply Lemma 11 to obtain 353

$$k_{p}k_{q}k_{p+q}\left(g\left(\frac{p}{k_{p}k_{q}k_{p+q}}\right) + g\left(\frac{p}{k_{p}k_{q}k_{p+q}}\right)\right) = k_{p}k_{q}k_{p+q} \cdot g\left(\frac{p+q}{k_{p}k_{q}k_{p+q}}\right)$$

$$= k_{p+q} \cdot g\left(\frac{p+q}{k_{p+q}}\right)$$

355

356 357

$$=g(p+q),$$

where the second equality follows by Fact 14, noting that $k_p k_q \in \mathbb{Z}^{>0}$ and $(p+q)/k_{p+q} \in B(0, 1/r)$. 358 Finally, by Lemma 12, g is well-defined within B(0, 1/r). Because g is defined by extrapolating 359

from its value within this ball, it is well-defined everywhere. 360

▶ Remark 15. This tester (and the same proof) will in fact work over any Gaussian $\mathcal{N}(0, \Sigma)$ for 361 arbitrary covariance matrix $\Sigma \in \mathbb{R}^{n \times n}$ by setting the value of r to be $50\sqrt{\|\Sigma^{-1}\|_2}$. 362

Algorithm 3: Distribution-Free Additivity Tester

Given :query access to $f : \mathbb{R}^n \to \mathbb{R}$, sampling access to an unknown distribution \mathcal{D} , and
sampling access to $\mathcal{N}(0, I)$;
1 Reject if TESTADDITIVITY(f) returns Reject ;
2 for $N_3 := O(1/\varepsilon)$ times do
3 Sample $p \sim \mathcal{D}$;
4 Reject if $f(p) \neq QUERY-g(p, f)$ or if $QUERY-g(p, f)$ returns Reject .
5 Accept.

363 3.2 Distribution-Free Tester

In this section, we prove Theorem 1 by adapting our tester for additivity over the standard Gaussian
 (Algorithm 1) to a distribution-free tester.

Assuming that we are able to draw samples from the standard Gaussian (or in fact any Gaussian), 366 the modification to Algorithm 1 is straight forward. Indeed, we will only have to modify Algorithm 1, 367 the two subroutines will remain the same. Let \mathcal{D} be our unknown distribution by which we will meas-368 ure the distance of f to an additive function. The high-level idea is to first run the TESTADDITIVITY 369 subroutine over the standard Gaussian. If it passes, then we know that with high probability g is 370 additive. We can obtain query access to g(p) (with high probability) as before by sampling points 371 $x \sim \mathcal{N}(0, I)$ and checking that the values of $k_p(f(p/k_p - x) + f(x))$ agree for all of the x that we 372 sample. To test whether f and g are ε -far according to \mathcal{D} it suffices to sample points $p \sim \mathcal{D}$ and check 373 whether f(p) and g(p) agree. 374

Our algorithm is given in Algorithm 3. We stress that both subroutines TESTADDITIVITY and QUERY- $g(p_i)$ are being performed over $\mathcal{N}(0, I)$, i.e., they do not use \mathcal{D} .

Proof of Theorem 1. The proof is nearly identical to the proof of Theorem 7. Again, observe that if f is an additive function then Algorithm 3 always accepts.

It remain to show that if f is ε -far from additive functions, then Algorithm 3 rejects with probability at least 2/3. If TESTADDITIVITY(f) accepts with probability at most 1/10, we can reject f with probability at least 1 - 1/10 > 2/3. Hence, we assume that TESTADDITIVITY(f) accepts with probability at least 1/10. By Lemma 8, the function g is additive and hence f is ε -far from g. Note that the probability that QUERY-g(p, f) fails to correctly recover g(p) is at most $\varepsilon/2$ by the same argument as before. It remains to bound the probability that Step 3 fails to reject, which is

$$\underset{\text{386}}{\overset{\text{B85}}{\text{B86}}} \qquad \left(\Pr_{p \sim \mathcal{N}(0,I)} \left[f(p) = g(p) \lor \text{QUERY-} g(p) \text{ fails to correctly recover } g(p) \right] \right)^{N_3} < \left(1 - \frac{\varepsilon}{2} \right)^{N_3} < \frac{1}{10} \left(1 - \frac{\varepsilon}{2} \right)^$$

by choosing the hidden constant in N_3 to be large enough, by the same argument as before. Therefore, Algorithm 3 rejects with probability at least 1 - 1/10 > 2/3.

4 Testing Linearity of Continuous Functions

In this section, we prove Theorem 2 by adapting the tester from the previous section (Algorithm 3) to test whether f is linear, given that f is a continuous function.

We would like to argue that if f is continuous and Algorithm 3 passes then g is in fact a linear function with high probability. However, in order to exploit continuity, we need f to satisfy f(-x) = -f(x) for every $x \in \mathbb{R}^n$. First, we will show how to argue that g is linear assuming that f(-x) = -f(x). After that, we will handle the case when this property does not hold.

22:12 Distribution-Free Testing of Linear Functions on \mathbb{R}^n

Lemma 16. If $f: \mathbb{R}^n \to \mathbb{R}$ is a continuous function satisfying f(-x) = -f(x) and the assumptions of Lemma 8 hold, then the function g is linear.

³⁹⁸ The proof will rely on the following claim which was originally proved by Darboux in 1875.

³⁹⁹ \triangleright Claim 17. Any additive function $f : \mathbb{R}^n \to \mathbb{R}$ which is continuous at a point $x_0 \in \mathbb{R}^n$ is a linear ⁴⁰⁰ function.

Proof. First, it is well-known that any additive function which is continuous at a point is continuous everywhere (see e.g., [4]). Next, we argue that the continuity of f implies that f(rx) = rf(x) for every $r \in \mathbb{R}$ and $x \in \mathbb{R}^n$. Because f is additive, this homogeneity holds for every $r \in \mathbb{Q}$, so it suffices to assume that r is irrational.

Fix $x \in \mathbb{R}^n$ and irrational r. Then for any $\zeta > 0$, we can always find $\tilde{r} \in \mathbb{Q}$ such that $|\tilde{r} - r| < \zeta$ and $\|\tilde{r}x - rx\|_2 < \zeta$. Now, by the continuity of f, for any $\xi > 0$ there exists $\zeta > 0$ such that whenever $\|\tilde{r}x - rx\|_2 < \zeta$, we have $|f(\tilde{r}x) - f(rx)| < \xi$. Now, take a sequence $\{\xi_i\}_i$ with $\xi_i \to 0$ and consider the corresponding sequence $\{\zeta_i\}_i$ with $\zeta_i \to 0$. Let $\{\tilde{r}_i\}_i$ with $r_i \in \mathbb{Q}$ be the sequence of approximations such that $|\tilde{r}_i - r| \le \zeta_i$ and $\|\tilde{r}_i x - rx\|_2 \le \zeta_i$. Then,

$$|f(rx) - rf(x)| \le |f(rx) - f(\tilde{r}_i x)| + |f(\tilde{r}_i x) - rf(x)| \le \xi_i + |\tilde{r}_i f(x) - rf(x)| \le \xi_i + \zeta_i |f(x)|.$$

 \leq

411 Because
$$\zeta_i, \xi_i \to 0, |f(rx) - rf(x)| \to 0$$
 and so $f(rx) = rf(x)$.

412 With this claim in hand, we are ready to prove Lemma 16.

⁴¹³ **Proof of Lemma 16.** Let f be a continuous function satisfying f(-x) = -f(x). By Lemma 8, ⁴¹⁴ the function g is additive. Conditioned on this event, we will show that the continuity of f implies ⁴¹⁵ that g is linear as well. To do so, we will argue that g is continuous at the origin and then appeal to ⁴¹⁶ Claim 17 to conclude that g is linear.

Let *B* be a ball of mass 1/2 (with respect to $\mathcal{N}(0, I)$) centred at the origin. Let $\{p_i\}_i$ be any sequence of points with $p_i \in B$, $\|p_i\|_2 \leq 1/r$ and $p_i \to 0$. Now, let $\{x_i\}_i$ be a sequence of points such that $g(p_i) = f(p_i - x_i) + f(x_i)$ and $x_i \in B$. Such a sequence exists because, by Lemma 8 Pr_{x \sim \mathcal{N}(0,I)} $[g(x) = f(p_i - x) + f(x)] \geq 1/2$ and so for every p_i there must exist such an x_i in *B*.

Let S be the ball centred at the origin with twice the radius of B. As S is compact and f is continuous, f is uniformly continuous on S. Thus for every $\xi > 0$, there exists $\zeta > 0$ such that $|f(p_i - x_i) - f(-x_i)| = |f(p_i - x_i) + f(x_i)| < \xi$ whenever $||(p_i - x_i) + x_i||_2 < \zeta$. Now, take a sequence $\{\xi_i\}_i$ with $\xi_i \to 0$ and consider the corresponding sequence $\{\zeta_i\}_i$. As $p_i \to 0$, for every i, there exists j such that $||(p_j - x_j) + x_j||_2 < \zeta_i$ which in particular implies that $|g(p_j)| = |f(p_j - x_j) + f(x_j)| < \xi_i$. Thus, $g(p_i) \to 0$, and g is continuous at the origin. By Claim 17, we can conclude that g is a linear function.

Now we consider the case when $f(-x) \neq -f(x)$ for some x. Luckily, in this case we can *force* f to satisfy f(-x) = -f(x). To do so, we test whether f is $\varepsilon/2$ -far from satisfying this property. If it is, then we reject f, otherwise, we can replace f with a function f' guaranteed to satisfy this property, by defining

432
$$f'(x) := \frac{f(x) - f(-x)}{2}.$$

We then continue to work over f' rather than f. Our modified algorithm is given in Algorithm 4, which uses Algorithm 5 as a subroutine.

⁴³⁶ \triangleright Claim 18. If FORCENEGATIVITY(f, D) accepts with probability at least 1/10, then $\Pr_{x \sim D}[f(x) = f'(x)] \ge 1 - \varepsilon$.

Algorithm 4: Distribution-Free Linear	ity Tester
---------------------------------------	------------

- **Given** :query access to a continuous $f : \mathbb{R}^n \to \mathbb{R}$, sampling access to an unknown distribution \mathcal{D} , and sampling access to $\mathcal{N}(0, I)$;
- 1 **Reject** if FORCENEGATIVITY(f, D) returns **Reject**;
- 2 Let f' be the returned function;
- **3 Reject** if TESTADDITIVITY(f') returns **Reject**;
- 4 for $N_4 := O(1/\epsilon)$ times do
- 5 Sample $p \sim \mathcal{D}$;
- 6 **Reject** if $f'(p) \neq QUERY-g(f', p)$ or if QUERY-g(f', p) returns **Reject**.
- 7 Accept.

Algorithm 5: Force Negativity Subroutine

1 Procedure FORCENEGATIVITY(f, D)Given :query-Access to $f: \mathbb{R}^n \to \mathbb{R}$ and sampling access to an unknown distribution D; 2 for $N_5 := O(1/\epsilon)$ times do 3 4 Sample $x \sim D$; 4 Reject if $f(-x) \neq -f(x)$; 5 Return a function $f': \mathbb{R}^n \to \mathbb{R}$ where $f'(x) := \frac{f(x) - f(-x)}{2}$;

⁴³⁸ Proof. Suppose for contradiction that $\Pr_{x \sim D}[f(x) = f'(x)] \leq 1 - \varepsilon$. Observe that for a point ⁴³⁹ $x \in \mathbb{R}, f'(x) \neq f(x)$ iff $f(-x) \neq -f(x)$. Therefore, by choosing the hidden constant in N_5 to be ⁴⁴⁰ large enough, the probability that all the sampled points x satisfy f(x) = -f(x) is at most

441
$$\left(\Pr_{x \sim \mathcal{D}}[f(-x) = f(x)]\right)^{N_5} < (1 - \varepsilon)^{N_5} \le \frac{1}{10},$$

442 which is a contradiction.

Therefore if FORCENEGATIVITY(f, D) accepts with probability at least 1/10, f and f' are $\varepsilon/2$ -close. Furthermore, because f is continuous and f' is the sum of continuous functions, f' is continuous as well, and so we can proceed with f' in place of f.

Proof of Theorem 2. First, observe that if f is linear then f = f' and Algorithm 4 always accepts. 446 Now, we show that if f is ε -far from linear functions, then Algorithm 4 rejects with probability at 447 least 2/3. If either the TESTADDITIVITY subroutine or the FORCENEGATIVITY subroutine passes 448 with probability at most 1/10, we can reject f with probability at least 1 - 1/10 > 2/3. Hence, we 449 assume both the subroutines pass with probability at least 1/10. Then by Lemma 18, f is $\varepsilon/2$ -close 450 to f', which means that f' is $\varepsilon/2$ -far from linear. Also by Lemma 16, because f' is continuous 451 and satisfies f'(-x) = -f'(x), the function q is linear, and so f' is $\varepsilon/2$ -far from q. Therefore, 452 Algorithm 4 rejects f with probability at least 1 - 1/10 > 2/3. 453

454 **5** Lower Bounds on Testing Linearity in the Sampling Model

In this section, we prove Theorem 3, that is, we show without query access, any tester requires a linear number of samples in order to test linearity and additivity over the standard Gaussian. We note that we can obtain the same lower bound for testing additivity just by replacing linearity with additivity in the proof.

 \leq

22:14 Distribution-Free Testing of Linear Functions on \mathbb{R}^n

By Yao's minimax principle it suffices to construct two distributions, \mathcal{D}_{yes} over linear functions and \mathcal{D}_{no} over functions which are (with probability 1) 1/3-far from linear such that any deterministic *n*-sample algorithm cannot distinguish between them with probability at least 2/3. Let $\delta \in \mathbb{R}^{\geq 0}$ be some parameter to be set later; we will think of δ as tiny. Instances from these two distributions are generated as follows:

464 \mathcal{D}_{ves} : Sample $w \sim \mathcal{N}(0, I)$ and return $f(x) := \langle w, x \rangle$.

465 \mathcal{D}_{no} : Sample $w \sim \mathcal{N}(0, I)$ and for every $x \in \mathbb{R}^n$ sample $\varepsilon_x \sim \mathcal{N}(0, \delta)$. Return $f(x) := \langle w, x \rangle + \varepsilon_x$.

The functions in the support of \mathcal{D}_{yes} are linear by definition. It remains to show that the instances in the support of \mathcal{D}_{no} are far from linear.

Lemma 19. With probability 1 any $f \sim D_{no}$ is 1/3-far from linear.

⁴⁷⁰ The proof of this lemma will hinge on the following claim.

 $_{\text{471}} \quad \rhd \text{ Claim 20.} \quad \text{Let } f \sim \mathcal{D}_{\text{no}}, \text{ for } x, y, z \sim \mathcal{N}(0, 1), \Pr[f(\frac{x-y}{2}) \neq f(\frac{x-z}{2}) + f(\frac{z-y}{2})] = 1.$

Proof. Observe that $\Pr\left[f\left(\frac{x-y}{2}\right) = f\left(\frac{x-z}{2}\right) + f\left(\frac{z-y}{2}\right)\right] = \Pr\left[\varepsilon_{(x-y)/2} = \varepsilon_{(x-z)/2} + \varepsilon_{(z-y)/2}\right]$, where the probability is over $\varepsilon_{(x-y)/2}, \varepsilon_{(x-z)/2}, \varepsilon_{(z-y)/2} \sim \mathcal{N}(0, \delta)$. Define the random variable $z := \varepsilon_{(x-y)/2} - \varepsilon_{(x-z)/2} - \varepsilon_{(z-y)/2}$, and note that z is distributed according to $\mathcal{N}(0, 3\delta)$. Then

475
$$\Pr_{z \sim \mathcal{N}(0,3)} \left[\varepsilon_{(x-y)/2} = \varepsilon_{(x-z)/2} + \varepsilon_{(z-y)/2} \right] = \Pr_{z \sim \mathcal{N}(0,3)} [z=0].$$

⁴⁷⁶ By standard arguments, we have $\Pr_{z \sim \mathcal{N}(0, 3\delta)}[z = 0] = 0$.

Proof of Lemma 19. Let f^* be the closest linear function to f. For a point $x \in \mathbb{R}^n$, say that f(x) is *bad* if $f(x) \neq f(x^*)$. Construct the following matrix: the rows are labelled by every triple $(\frac{x-y}{2}, \frac{x-z}{2}, \frac{z-y}{2})$ and there are three columns. The entries at row $(\frac{x-y}{2}, \frac{x-z}{2}, \frac{z-y}{2})$ are $f(\frac{x-y}{2})$, $f(\frac{x-z}{2})$, and $f(\frac{z-y}{2})$. Note that because $x, y, z \sim \mathcal{N}(0, 1)$, the points $\frac{x-y}{2}, \frac{x-z}{2}, \frac{z-y}{2}$ are distributed according to $\mathcal{N}(0, 1)$.

Henceforth, we will measure mass in terms of probability mass over $\mathcal{N}(0, 1)$. By Claim 20, the probability that each row contains a bad entry is 1. Therefore, there must be some column for which the probability mass of the bad entries is at least 1/3. This implies that a mass of at least 1/3 of fmust be changed to obtain f^* . Because f^* is the closest linear function to f, this implies that f is 1/3-far from linear.

Having defined our distributions over linear and far-from-linear functions, it remains to argue that no algorithm receiving n samples can distinguish between them with high probability.

Proof of Theorem 3. Let \mathcal{D} be the distribution that with probability 1/2 draws $f \sim \mathcal{D}_{yes}$ and otherwise draws $f \sim \mathcal{D}_{no}$. Let A be any deterministic algorithm which receives n samples $x_1, \ldots, x_n \sim \mathcal{N}(0, I)$. By Yao's minimax principle, it suffices to show that A cannot correctly distinguish which distribution of the distributions \mathcal{D}_{yes} or \mathcal{D}_{no} a given sample $f \sim \mathcal{D}$ comes from with probability at least 2/3. That is, we would like to show that

$$494 \qquad \left| \Pr_{\substack{f \sim \mathcal{D}_{\text{yes}} \\ x_1, \dots, x_n \sim \mathcal{N}(0,I)}} [A(f(x_1), \dots, f(x_n)) = 1] - \Pr_{\substack{f \sim \mathcal{D}_{\text{no}} \\ x_1, \dots, x_n \sim \mathcal{N}(0,I)}} [A(f(x_1), \dots, f(x_n)) = 1] \right|$$
(4)

⁴⁹⁶ is o(1). Suppose for contradiction that an algorithm A exists that with probability at least 2/3⁴⁹⁷ distinguishes these distributions.

Observe that the (4) can be bounded from above by the total variation distance between the distributions $(f^y(x_1), \ldots, f^y(x_n))$ for $f^y \sim \mathcal{D}_{yes}$, and $(f^n(x_1), \ldots, f^n(x_n))$ for $f^n \sim \mathcal{D}_{no}$, for

◀

⁵⁰⁰ $x_1, \ldots, x_n \sim \mathcal{N}(0, I)$, as applying the algorithm A can only make the total variation distance ⁵⁰¹ smaller. By the definition of \mathcal{D}_{yes} and \mathcal{D}_{no} , this means bounding the total variation distance between ⁵⁰² $(w_y^{\top} x_1, \ldots, w_y^{\top} x_n)$ and $(w_n^{\top} x_1 + \varepsilon_{x_1}, \ldots, w_n^{\top} x_n + \varepsilon_{x_n})$, where $w_y \sim \mathcal{D}_{\text{yes}}$ and $w_n \sim \mathcal{D}_{\text{no}}$

Now, let $X \in \mathbb{R}^n$ be the matrix whose rows are x_1, \ldots, x_n . Because $w_y, w_n \sim \mathcal{N}(0, I)$ and $\varepsilon_{x_i} \sim \mathcal{N}(0, \delta)$, it follows that

$$(w^{\top}x_1,\ldots,w^{\top}x_n) \sim \mathcal{N}(0,XX^{\top}),$$

$$\sup_{500} \qquad (w_n^{\top} x_1, \dots, w_n^{\top} x_n) + (\varepsilon_{x_1}, \dots, \varepsilon_{x_n}) \sim \mathcal{N}(0, XX^{\top} + \delta I).$$

508 Therefore,

509 $(4) \leq \mathrm{d}_{\mathrm{TV}}(\mathcal{N}(0, XX^{\top}), \mathcal{N}(0, XX^{\top} + \delta I)).$

To bound this distance we will appeal to Pinkser's inequality and Lemma 5. Thus, it will be useful to first record some facts about the covariance matrices of these distribution. First, we show that the rows of the matrix X are linearly independent with high probability.

▶ Fact 21. $\Pr_{x_1,...,x_n \sim \mathcal{N}(0,1)}[\operatorname{span}(x_1,...,x_n) = \mathbb{R}^n] = 1.$

⁵¹⁴ It follows that the covariance matrices of these two distributions are positive definite with high ⁵¹⁵ probability.

⁵¹⁶ \triangleright Claim 22. With probability 1 the matrices XX^{\top} and $XX^{\top} + \delta I$ are positive definite.

Proof. That $XX^{\top} \succ 0$ is immediate from Fact 21, which implies that rows of X are linearly independent with probability 1. Let $\lambda_1, \ldots, \lambda_n$ be the eigenvalues of XX^{\top} . To prove that $XX^{\top} + \delta I \succ 0$ note that adding δI simply adds δ to each of the eigenvalues. Thus, the eigenvalues of $XX^{\top} + \delta I$ are all positive.

With these facts in hand we turn to bounding the total variation distance between $\mathcal{N}(0, XX^{\top})$ and $\mathcal{N}(0, XX^{\top} + \delta I)$. Denote by $\Sigma_{\text{yes}} := XX^{\top}$ and $\Sigma_{\text{no}} := XX^{\top} + \delta I$. By Pinkser's inequality (Theorem 4) and Lemma 5,

⁵²⁴
$$d_{\mathrm{TV}}\left(\mathcal{N}(0, XX^{\top}), \mathcal{N}(0, XX^{\top} + \delta I)\right) \leq \sqrt{\frac{1}{4}\left(\log\left(\frac{\det \Sigma_{\mathrm{yes}}}{\det \Sigma_{\mathrm{no}}}\right) + \operatorname{tr}\left(\Sigma_{\mathrm{yes}}^{-1}\Sigma_{\mathrm{no}}\right) - n\right)}.$$

525 We will bound each of these terms separately.

Bounding the Determinant.

 $\det \Sigma_{n\alpha}$

For simplicity of notation, we will bound the inverse of $\det(\Sigma_{\rm ves})/\det(\Sigma_{\rm NO})$ below. We have

$$\frac{1}{\det \Sigma_{\text{yes}}} = \frac{1}{\det(XX^{\top})}$$
$$= \det\left(XX^{\top}(XX^{\top})^{-1} + \delta(XX^{\top})^{-1}\right)$$

 $\det(XX^{\top} + \delta I)$

529 530

$$= \det\left(I + \delta\left(XX^{\top}\right)^{-1}\right).$$

⁵³² \triangleright Claim 23. If A is a diagonalizable matrix with eigenvalues $\lambda_1, \ldots, \lambda_n$ then det $(A + I) = \prod_{i=1}^{n} (\lambda_i + 1)$.

Applying this claim, we have $\det(I + \delta(XX^{\top})^{-1}) = (\delta\lambda_1^{-1} + 1) \dots (\delta\lambda_n^{-1} + 1)$, where $\lambda_1, \dots, \lambda_n$ are the eigenvalues of XX^{\top} . By Claim 22 the matrix XX^{\top} is positive definite and so $\lambda_i > 0$ for all *i*. Therefore, $(\delta\lambda_i^{-1} + 1) > 1$ for all *i*, and we can conclude that $\det \Sigma_n / \det \Sigma_{yes} > 1$. Thus we can upper bound $\det \Sigma_{yes} / \det \Sigma_{n}$ by 1.

538 Bounding the Trace.

539 Next, we bound

540
$$\operatorname{tr}\left(\Sigma_{\operatorname{yes}}^{-1}\Sigma_{\operatorname{no}}\right) = \operatorname{tr}\left(\left(XX^{\top}\right)^{-1}\left(XX^{\top} + \delta I\right)\right)$$
541
$$= \operatorname{tr}\left(I + \delta\left(X^{\top}\right)^{-1}X^{-1}\right)$$

541

$$= \operatorname{tr}\left(I + \delta \operatorname{tr}\left(\left(X^{\top}\right)^{-1}X^{-1}\right)\right)$$
$$\leq \operatorname{tr}(I) + \delta \operatorname{tr}\left(\left(X^{\top}\right)^{-1}X^{-1}\right)$$

542

$$= n + \delta \sum_{i,j} \left(X_{i,j}^{-1} \right)^2$$

$$\leq n + \delta n^2 \cdot \lambda_{\max} (X^{-1})^2,$$

where λ_{\max} is the largest eigenvalue of X^{-1} . Noting that the eigenvalues of X^{-1} are the inverse of the eigenvalues of X, we have tr $(\Sigma_{\text{yes}}^{-1}\Sigma_{\text{no}}) \leq n + \delta n^2 / \lambda_{\min}(X)^2$. Setting $\delta := C \lambda_{\min}(X)^2 / n^2$ for some tiny C > 0 to be set later, we can conclude that tr $(\Sigma_{\text{ves}}^{-1}\Sigma_{\text{no}}) \leq n + C$.

549 Completing the proof.

⁵⁵⁰ Putting our previous bounds together we conclude that

551
$$d_{\mathrm{TV}}\left(\mathcal{N}(0, XX^{\top}), \mathcal{N}(0, XX^{\top} + \delta I)\right) \leq \sqrt{\frac{1}{4}\left(\log(1) + n + C - n\right)} = \frac{1}{2}C^{1/2}.$$

552 By our previous argument we have

$$(4) \le \mathrm{d}_{\mathrm{TV}}\left(\mathcal{N}(0, XX^{\top}), \mathcal{N}(0, XX^{\top} + \delta I)\right) \le \frac{1}{2}C^{1/2}.$$

Setting $C < (2/3)^2$ contradicts our assumption of the existence of an algorithm A which distinguishes a sample drawn from \mathcal{D}_{yes} from one drawn from \mathcal{D}_{no} with probability at least 2/3, completing the proof.

Finally, observe that the same proof goes through for testing additivity as well. Indeed, \mathcal{D}_{yes} is supported on additive functions, while \mathcal{D}_{no} is supported on functions which are far from additive with probability 1.

Corollary 24. Any sampler for additivity of functions $f : \mathbb{R}^n \to \mathbb{R}$ requires $\Omega(n)$ samples when $\mathcal{D} = \mathcal{N}(0, I)$.
